Abstract. In a GraphQL Web API, a so-called GraphQL schema defines the types of data objects that can be queried, and so-called resolver functions are responsible for fetching the relevant data from underlying data sources. Thus, we can expect to use GraphQL not only for data access but also for data integration, if the GraphQL schema reflects the semantics of data from multiple data sources, and the resolver functions can obtain data from these data sources and structure the data according to the schema. However, there does not exist a semantics-aware approach to employ GraphQL for data integration. Furthermore, there are no formal methods for defining a GraphQL API based on an ontology. In this work, we introduce a framework for using GraphQL in which a global domain ontology informs the generation of a GraphQL server that answers requests by querying heterogeneous data sources. The core of this framework consists of an algorithm to generate a GraphQL schema based on an ontology and a generic resolver function based on semantic mappings. We provide a prototype, OBG-gen, of this framework, and we evaluate our approach over a real-world data integration scenario in the materials design domain and two synthetic benchmark scenarios (Linköping GraphQL Benchmark and GTFS-Madrid-Bench). The experimental results of our evaluation indicate that: (i) our approach is feasible to generate GraphQL servers for data access and integration over heterogeneous data sources, thus avoiding a manual construction of GraphQL servers, and (ii) our data access and integration approach is general and applicable to different domains where data is shared or queried via different ways.

Keywords: Data Integration, Ontology, GraphQL

1. Introduction

GraphQL is a conceptual framework to build APIs for Web and mobile applications [1]. It was publicly released by Facebook in 2015 and, since then, the GraphQL ecosystem\textsuperscript{1} has grown tremendously in terms of li-
braries supporting different programming languages (such as Python, Java and JavaScript), tools (such as Apollo and GraphiQL), and adopters (such as Airbnb, IBM and Twitter). The framework introduces the notion of a schema. Such a schema of a GraphQL API contains type definitions which specify what data objects can be retrieved from the API. The framework also contains a form of query language for expressing such data retrieval requests. A third component of GraphQL are resolver functions, which are typically used for executing GraphQL queries in a GraphQL server. That is, such resolvers specify—in terms of program code—how data related to the various elements of a GraphQL schema has to be fetched from underlying data sources.

GraphQL could be used to integrate data from different data sources by building a GraphQL server over these sources, in which the GraphQL schema provides a view over data from multiple sources, and the resolver functions contain implementations for accessing multiple sources. However, a semantics-aware approach to employing GraphQL for data integration does not exist. The approaches in [2] and [3] introduce how to use GraphQL for data federation. The semantics of data are not explicit in a machine-processable form which means the developer needs to write program code (i.e., resolver functions) to populate the various elements of a GraphQL schema. Furthermore, there are no formal methods for defining a GraphQL schema. The developers have to define a GraphQL schema manually. The aim of this work is to provide a semantics-aware approach to employ GraphQL for data integration, with formal methods to generate the GraphQL server.

**Research problem:** This article focuses on the following question: How can ontologies be leveraged to generate GraphQL APIs for semantics-aware data access and data integration? We pursue the objectives: (i) to provide an ontology-driven data access and integration approach in which a GraphQL server accesses underlying data sources by providing an integrated view of the data; (ii) to formally generate GraphQL servers automatically to avoid manual constructions of the servers.

**Contributions:** To address the research question, we propose a framework for GraphQL-based data access and integration in which an ontology drives the generation of a GraphQL server. More specifically, given an ontology as an integrated view of data from multiple data sources, the first contribution is that we propose and implement a method for generating a GraphQL schema based on semantic assets in this ontology such that the schema becomes a view of the data to be integrated. Then, the second contribution is that we introduce a generic approach to create a GraphQL server that is capable to get data from the corresponding data sources by relying on semantic mappings that use the ontology.

The remainder of the article is organized as follows. We provide the relevant background regarding ontologies, description logics, data integration and GraphQL in Section 2. Then we outline the proposed GraphQL-based framework in Section 3 and elaborate on the implementation of this framework in Sections 4 and 5. Section 6 introduces related work. Section 7 presents an evaluation based on a real-world data integration scenario in the materials design domain and evaluations based on two synthetic benchmark scenarios, the Linköping GraphQL Benchmark (LinGBM) and GTFS-Madrid-Bench. Section 8 discusses the strengths and limitations of our approach, and introduces the directions for future work. Finally in Section 9, we present concluding remarks.

## 2. Background

This section provides background information on ontologies, description logics, data integration and GraphQL.

### 2.1. Ontologies and Description Logics

The term *ontology* originates in philosophy, in which it is the science of what is, of the kinds and structures of objects, properties, and relationships in every area of reality [5, 6]. Ontologies can be viewed, intuitively, as defining the terms, relations, and rules that combine these terms and relations in a domain of interest [7]. Through
ontologies, people and organizations are able to communicate by establishing a common terminology. They provide the basis for interoperability between systems and are applicable as an index to a repository of information as well as a query model and a navigation model for data sources. Moreover, they are often used as a foundation for integrating data sources, thereby alleviating the heterogeneity issue. The benefits of using ontologies are their improved reusability, share-ability and portability across platforms, as well as their increased maintainability and reliability. On the whole, ontologies allow a field to be better understood and allow information in that field to be handled much more effectively and efficiently (e.g., knowledge representation for bioinformatics discussed in [8]).

From a knowledge representation point of view, ontologies usually contain four components: (i) concepts that represent sets or classes of entities in a domain, (ii) instances that represent the actual entities, (iii) relations, and (iv) axioms that represent facts that are always true in the topic area of the ontology. Relations represent relationships among concepts. Axioms represent domain restrictions, cardinality restrictions, or disjointness restrictions. Depending on the components and information related to the components they contain, ontologies can be classified.

Figure 1 represents an example ontology for the university domain. The open-headed arrows represent axioms that represent is-a relationships that is, if A is a B, then all entities belonging to concept A also belong to concept B. We say that A is a sub-concept of B. In this example Professor is a sub-concept of Author. Therefore, all Professor entities are Author entities. The closed-headed arrows represent general relations among concepts other than is-a relations. For instance, the Professor concept has a connection to the University concept represented by the doctoralDegreeFrom relation. Additionally, a relation can exist between a concept and a data type reference. For instance, University has a connection to the data type reference xsd:string represented by the UniversityID relation. This means that each entity of the University concept can be associated with a string type value by having a UniversityID connection.

To formally define the above concepts and relationships, we need representation languages. Description logics (DL) are a family of knowledge representation languages. There are three basic building blocks of such a language, namely: (i) atomic concepts (unary predicates) such as University and Department, (ii) atomic roles (binary predicates) such as departments, and (iii) individuals (constants) [9]. Complex concepts and roles can be built by using atomic concepts and logical constructors (e.g., conjunction (\(\sqcap\)), disjunction (\(\sqcup\)), universal restriction (\(\forall\)) and existential restriction (\(\exists\)). Axioms can be defined using general concept inclusions (GCI).

\[
\text{University} \sqsubseteq \forall \text{departments}.\text{Department}
\]

This fact expresses that University is a sub-concept of the concept \(\forall \text{departments}.\text{Department}\), which means that all entities that may have departments relations to entities and if so, these latter entities must be \text{Department} concept.

An assertion \text{University}!(Linköping University) means that the instance Linköping University belongs to the University concept. A DL TBox is a finite set of GCIs and a DL ABox is a finite set of assertions.

### 2.2. Data Integration

Data integration deals with combining data that resides at multiple different sources [10–12]. Ideally, a data integration system should enable unified access to a number of data sources [10, 12]. Formally, according to [10], a data integration system can be formalized as a triple \((G, S, M)\), where,

\[
\begin{align*}
G & \text{ is the global schema, expressed in a language } \mathcal{L}_G \text{ over an alphabet } \mathcal{A}_G; \\
S & \text{ is the source schema, expressed in a language } \mathcal{L}_S \text{ over an alphabet } \mathcal{A}_S; \\
M & \text{ is the mapping between } G \text{ and } S, \text{ constituted by a set of assertions that define mappings from queries over the source schema } S \text{ to queries over the global schema } G (\text{similarly for mappings from queries over } G \text{ to } S).
\end{align*}
\]
queries over $S$). Such a mapping specifies correspondences between concepts in the global schema and those in the source schema.

Ontology-based data integration (OBDI) is a form of data integration in which an ontology plays the role of a global schema that captures domain knowledge [13]. Usually, in an information system with only one single data source, the formal treatment of OBDI is identical to that of ontology-based data access (OBDA) [13, 14]. In this article, we generally refer to both OBDI and OBDA as OBDA. OBDA, as a semantic technology, aims to facilitate access to different underlying data sources [15]. Traditionally, these underlying data sources are considered to be relational databases. Ontologies play the role of global views over multiple data sources. There are different ways to implement an OBDA system. Generally, these systems can be categorized into two types, namely, data warehouse-based approaches and virtual approaches. These two categories of methods both make use of semantic mappings in order to overcome the differences between ontologies and local schemas, but in different ways [16, 17]. In a data warehouse-based approach, data from multiple sources are usually loaded or stored in a centralized storage, which is the warehouse [12, 18], based on semantic mappings. We refer to the data in such warehouses as materialized data. Depending on the aims or functionalities of a system, the materialized data could be stored in local databases or transformed into RDF graphs. Therefore, queries are evaluated against the materialized data. In a virtual approach, data is retained at the original sources and mediators are used to translate queries defined in terms of a global or mediated schema into queries defined in terms of each data source’s local schema, based on semantic mappings. Therefore, queries are evaluated and executed against each data source. SPARQL queries are widely supported by data integration systems that use ontologies as global schemas.

A number of semantic mapping definition languages have been proposed over the years. One such language is R2RML (RDB to RDF Mapping Language), one of the two recommendations by the RDB2RDF W3C Working Group to define semantic mappings [19]. It supports transformation rules defined by users, while the other recommendation, Direct Mapping [20], does not. Another language is RDF Mapping Language (RML) [21, 22], which allows underlying data in formats beyond relational databases and is a superset of R2RML. RML allows data from CSV, JSON, and XML data sources. In our work we make use of RML and we introduce RML in more details in Section 5.2.

2.3. GraphQL

GraphQL schemas and GraphQL resolver functions are basic building blocks in the implementations of GraphQL servers. The former describe how users can retrieve data using GraphQL APIs. The latter contain program code including how to access data sources and structure the obtained data according to the schema. We introduce GraphQL schemas and GraphQL resolver functions in Section 2.3.1 and Section 2.3.2, respectively.

2.3.1. GraphQL Schemas

In a GraphQL API, the GraphQL schema defines types, their fields, and the value types of the fields. Such a schema represents a form of vocabulary supported by a GraphQL API rather than specifying what the data instances of an underlying data source may look like and what constraints have to be guaranteed [23]. There are six different (named) type definitions in GraphQL, which are scalar type, object type, interface type, union type, enum type and input object type. Listing 1 depicts a GraphQL schema example.

An object type represents a list of fields and each field has a value of a specific type such as object type or scalar type. A scalar is used to represent a value such as a string. In Listing 1, there are three basic object type definitions, which are University (line 1 to line 4), Department (line 5 to line 8), and Professor (line 12 to line 15). They all have field definitions which represent the relationships to scalar types or to other object types. For instance, the University type has a field definition UniversityID of which the value type is String (line 2), and a field definition departments of which the value type is a list of Departments (line 3). GraphQL allows defining abstract types by supporting the interface type and the union type. An interface type defines a list of fields and allows object types to implement. An object type can then implement an interface type with the requirement

---

5https://www.w3.org/TR/r2rml/
6https://www.w3.org/2001/sw/rdb2rdf/
that the object type includes all fields defined by the interface type. The schema in Listing 1 contains an interface
type, Author with an AuthorID field of which the value type is String (line 9 to line 11). The object type
Professor implements Author and must have the same definition for AuthorID field (line 13) as that in
Author. A union type defines a list of possible types. An enum type describes the set of possible values that are in
scalars. For more details of union and enum types, we refer the reader to the latest GraphQL specification in [1].

GraphQL allows fields to accept arguments to configure their behavior [1]. These arguments can be
defined by input object types. An input object type defines an input object with a set of input fields; the in-
put fields are either scalars, enums, or other input objects. This allows arguments to accept arbitrarily com-
plex structs, which can capture notions of filtering conditions. For instance, according to the definitions of
UniversityFilter (line 16 to line 22) and StringFilter (line 30 to line 36), we can define an input
argument as UniversityID:{_eq:"u1"} to capture the meaning of "UniversityID is equal to 'u1'", where
_eq represents the equal to operator. In our approach, _and, _or and _not are used to represent boolean ex-
const UniversityList = (university_id) => {
  let query = "";
  if(university_id)
    query = db_connection.select().from('university').where('id', university_id);
  else
    query = db_connection.select().from('university');
  return query.then(rows => rows.map(row => new University(row)));
data sources may be based on different schemas and formats and may be accessed in different ways (e.g., as tabular data accessed via SQL queries or as JSON-formatted data accessed via API requests). To address the heterogeneity, the framework relies on an ontology that provides an integrated view of the data from the different sources, and corresponding semantic mappings that define how the data from the underlying data sources is interpreted or annotated by the ontology (arrows (a) and (b)). Furthermore, two processes are defined. The first process generates the GraphQL server. The second process deals with answering queries and is performed after the GraphQL server is set up. In accordance with these two processes, there are two types of intended users or developers in the framework. One type is users or developers of the GraphQL server generator, who should have prior knowledge of the ontology, semantic mappings and the domain. The other type is end users using a GraphQL server for data access and integration, who may or may not be familiar with the Semantic Web or ontologies. For the purpose of writing GraphQL queries, they need basic prior knowledge of GraphQL, which can be learned from the self-documenting API of the generated GraphQL server showing the schema. We introduce more details about these two processes in Section 3.2 and Section 3.3, respectively.

### 3.2. GraphQL Server Generation Process

This process includes generating both a GraphQL schema for the API provided by the server (arrow (i)) and a generic resolver function (arrow (ii)). Given an ontology as an integrated view of data from multiple data sources, we propose a method for generating a GraphQL schema based on this ontology, with the result that the schema becomes a view of the data to be integrated. Additionally, we propose a generic implementation of resolver functions that takes semantic mappings as inputs, so that the server is able to get data from underlying data sources. In Sections 4 and 5, we elaborate on the implementation of our approaches for generating a GraphQL schema and the generic resolver function, respectively. This GraphQL server generation process does not need to be repeated unless the ontology or the semantic mappings change. After this generation process, the GraphQL server can be set up.

This process requires users or developers who are familiar with the query mechanisms of underlying data sources, domain ontologies that can be used for data access or integration. Consequently, they can define the scope of the ontology that will be used for generating the GraphQL schema for the server, as well as the semantic mappings that will be used for generating the generic resolver function. This type of automatic generation of GraphQL servers based on ontologies and semantic mappings can also benefit general GraphQL application developers, since it can eliminate the need to build GraphQL servers from scratch.

### 3.3. GraphQL Query Answering Process

During this process the query is validated against the GraphQL schema (arrow (i)); the underlying data sources are accessed via resolver functions, the retrieved data is combined, the data is structured according to the schema (arrows (2) and (3)); and finally the query result is returned (arrow (4)).
A GraphQL query example and corresponding query result are shown in Listing 3 and Listing 4, respectively. The example query is: "Get the university including the head of each department where the UniversityID is 'u1'". The query takes as an input an argument defined as filter:{(UniversityID:{_eq:"u1"})}, which follows the syntax of the input object type UniversityFilter. As mentioned in Section 2.3.1, the meaning of an input argument defined as an input object type is essentially determined by the program code of the resolver functions. Thus the query example shown in Listing 3 illustrates one way that we make use of input objects to represent filtering conditions. In general, however, the input object types can be used in various ways for any field, depending on the implementation of the GraphQL server.

As mentioned earlier, domain users are the intended users of GraphQL servers, regardless of whether they have prior knowledge of the Semantic Web or ontologies. In order to write GraphQL queries, they only need to have a basic understanding of GraphQL, which can easily be explored via the GraphQL API provided by the server.

4. Ontology-Based GraphQL Schema Generation

As mentioned in Section 2.3.1, the GraphQL schema represents a form of vocabulary supported by the GraphQL API rather than specifying what the data instances of an underlying data source may look like and what constraints have to be guaranteed. Therefore, we focus on GraphQL language features supporting semantics-aware and integrated data access, namely how data can be queried, rather than reflecting the semantics of a complex knowledge representation language in the context of a GraphQL schema. Section 4.1 introduces how a GraphQL schema is formalized, and Section 4.2 introduces how an ontology is represented via a description logic TBox. Given an ontology represented in a description logic TBox, the concept and role names can be used to generate types and fields in a GraphQL schema. The general concept inclusions in a description logic TBox can be used to specify how to connect malized, and Section 4.2 introduces how an ontology is represented via a description logic TBox. Given an ontology

4.1. GraphQL Schema Formalization

According to [23, 24], a GraphQL schema can be defined over five finite sets. These five sets are $\mathcal{F} \subseteq \mathcal{Fields}$, $\mathcal{A} \subseteq \mathcal{Arguments}$, $\mathcal{T} \subseteq \mathcal{Types}$, $\mathcal{S} \subseteq \mathcal{ Scalars}$, and $\mathcal{D} \subseteq \mathcal{Directives}$ where $\mathcal{T}$ is the disjoint union of $\mathcal{O}_t$ (object types), $\mathcal{I}_t$ (interface types), $\mathcal{U}_t$ (union types), $\mathcal{IO}_t$ (input object types) and $\mathcal{S}$ (scalar types). $\mathcal{Fields}$, $\mathcal{ Arguments}$, $\mathcal{ Types}$, and $\mathcal{Directives}$ are pairwise disjoint, countably infinite sets representing field names, argument names, type names, and directive names, respectively. $\mathcal{ Scalars}$, which is a subset of $\mathcal{ Types}$, represents five built-in scalar types, which are Int, Float, String, Boolean, and ID. Moreover, the GraphQL schema definition language introduces non-null types and list types, called wrapping types, according to types in $\mathcal{ Types}$. Given a type $t$ belonging to $\mathcal{ Types}$, the former is denoted as $t!$, while the latter is denoted as $[t]$. $\mathcal{ S}$ is used to denote the set of all types that can be formed by wrapping the types in $\mathcal{ T}$, and $\mathcal{ S}$ denotes the set of all types that can be formed by wrapping the scalar types in $\mathcal{ S}$. In our current work, considering the knowledge representation language we use
for the ontology (see next section), our GraphQL schema generator will neither produce union types nor directive definitions. Therefore, a GraphQL schema $\mathcal{S}$ is defined over $(F, A, T, S)$ consisting of two assignments that are type $\mathcal{S}$ and implementation $\mathcal{S}$:

- $\text{type}_{\mathcal{S}} = \text{type}_{\mathcal{S}}^F \cup \text{type}_{\mathcal{S}}^\mathcal{T}$ where,

  * $\text{type}_{\mathcal{S}}^F : (O_T \cup I_T \cup IO_T) \times F \rightarrow T \cup W_T$, which is a partial function since a type has a set of fields which is a subset of $F$, assigns a type to each field that is defined for an object type, an interface type or an input object type.

  * $\text{type}_{\mathcal{S}}^\mathcal{T} : \text{dom}(\text{type}_{\mathcal{S}}^F) \times A \rightarrow S \cup \mathcal{W}_S \cup IO_T$, which is a partial function since a field has a set of arguments which is a subset of $A$, assigns a type to every argument of fields that are defined for a type.

- $\text{implementation}_{\mathcal{S}} : I_T \rightarrow 2^{O_T \cup I_T}$ assigns a set of object types or interface types to every interface type.

Listing 5 illustrates a formalized representation of the GraphQL schema shown in Listing 1. In the formalization, we have sets $F, A, I_T, O_T, S$ and $IO_T$, which contains all the field names, argument names, interface type names, object type names, scalar type names and input object type names, respectively. Additionally, the formal-

```plaintext
- F = {UniversityID, departments, DepartmentID, head, AuthorID, doctoralDegreeFrom, _and, _or, _not, _eq, _in, _neg, _nin, _like, UniversityList, DepartmentList, AuthorList, ProfessorList};
- A = {filter};
- T = I_T \cup O_T \cup S \cup IO_T; where,

  * I_T = {Author},
  * O_T = {Query, University, Department, Professor},
  * S = {String},
  * IO_T = {UniversityFilter, DepartmentFilter, StringFilter};

- \text{type}_{\mathcal{S}} = \text{type}_{\mathcal{S}}^F \cup \text{type}_{\mathcal{S}}^\mathcal{T}$ where,

  * \text{type}_{\mathcal{S}}^F = \{(University, UniversityID) \rightarrow String,

    (Department, DepartmentID) \rightarrow String,

    (Department, head) \rightarrow String,

    (Author, AuthorID) \rightarrow String,

    (Professor, AuthorID) \rightarrow String,

    (Professor, doctoralDegreeFrom) \rightarrow [University],

    (UniversityFilter, UniversityID) \rightarrow StringFilter,

    (StringFilter, departments) \rightarrow DepartmentFilter,

    (StringFilter, _and) \rightarrow [UniversityFilter],

    (StringFilter, _or) \rightarrow [UniversityFilter],

    (StringFilter, _not) \rightarrow UniversityFilter,

    (DepartmentFilter, DepartmentID) \rightarrow StringFilter,

    (StringFilter, _and) \rightarrow DepartmentFilter,

    (StringFilter, _or) \rightarrow [DepartmentFilter],

    (StringFilter, _not) \rightarrow DepartmentFilter,

    (StringFilter, _eq) \rightarrow String,

    (StringFilter, _in) \rightarrow [String],

    (StringFilter, _neg) \rightarrow String,

    (StringFilter, _nin) \rightarrow [String],

    (StringFilter, _like) \rightarrow String,

    (Query, UniversityList) \rightarrow [University],

    (ProfessorList) \rightarrow [Professor];

- \text{implementation}_{\mathcal{S}} = \{Author \rightarrow \{Professor\}\}.
```

ABox: $P(a)$, $a^T \in P^T$  
Role assertion: $R(a,b)$, $(a^T, b^T) \in R^T$  
Attribute assertion: $A(a,v)$, $(a^T, v^T) \in A^T$  

The syntax and semantics of the description logic used in our approach are shown in Table 1. The introduction of datatypes is based on the work presented in [26] and [27]. Let $N_C$, $N_R$, $N_A$, and $D$ be disjoint finite sets of concept names, role names, attribute names, and datatype names respectively. An interpretation $I$ consists of a non-empty set $\Delta^T$ representing the domain of individuals, and an interpretation function $\Delta^T$. In addition, the interpretation includes an interpretation domain for data values $\Delta^D_0$ which is disjoint from the domain of individuals $\Delta^T$ [26]. A datatype, such as an integer, is interpreted as a subset of $\Delta^D_0$ and a value such as the integer 5 is interpreted as an element of $\Delta^D_0$. Thus, the interpretation function $\Delta^T$ assigns to each atomic concept $P \in N_C$ a subset $P^T \subseteq \Delta^T$, to each $d \in D$ a set $d^T \subseteq \Delta^D_0$, to each role $r \in N_R$ a relation $r^T \subseteq \Delta^T \times \Delta^T$, to each attribute $a \in N_A$ a relation $a^T \subseteq \Delta^T \times \Delta^D_0$, to each individual name $i$ an element $i^T \in \Delta^T$, and to each data value $v$ an element $v^T \in \Delta^D_0$.

A TBox over $N_C$, $N_R$, $N_A$ and $D$ is a finite set of general concept inclusions (GCI) where each GCI is a statement in the form of $B \sqsubseteq C$, where $B$ and $C$ are concepts. For generating GraphQL schemas, we use normalized TBoxes

$$NF_1 : P \sqsubseteq Q \quad NF_2 : P \sqsubseteq \forall r.Q \quad NF_3 : P \sqsubseteq 1.r.Q \quad NF_4 : P \sqsubseteq \forall a.d \quad NF_5 : P \sqsubseteq 1.a.d \quad (1)$$
that contain only GCIs in the normal forms given in formula 1 where \( P, Q \in N_C, r \in N_R, a \in N_A, \) and \( d \in D \). There exist normalization rules to obtain such a TBox (e.g., an axiom \( P \subseteq Q \cap M \) is converted to two axioms, \( P \subseteq Q \) and \( P \subseteq M \)) [28]. Baader et al. show that such normalization rules can preserve a conservative extension of a TBox in \( \mathcal{FL}_0 \) [29]. A conservative extension guarantees that subsumptions according to the original TBox coincide with those with respect to the normalized TBox. An example TBox input is shown in Listing 6.

### 4.3. Schema Generator Algorithm

Algorithm 1 shows the details to generate a GraphQL schema. The output for the example is the schema shown in Listing 1. First, the algorithm iterates over the concept names in \( N_C \) (line 1 to line 5). For each concept, such as University in the TBox, the concept name (University) is used as the name of an object type to be generated (line 2); the term concatenated with ‘Filter’ is used as the name of an input type (UniversityFilter) to be generated (line 3); the term concatenated with ‘List’ is used as the name of a field (UniversityList) of the Query type (line 4). Additionally, each such field of the Query type is assigned an argument named ‘filter’, with a type that is the corresponding input type (e.g., filter:UniversityFilter to UniversityList) (line 5).

Next, the algorithm iterates over GCIs in the TBox (line 6 to line 30). For a GCI in the form of \( C \sqsubseteq A \sqcap B \) (line 6), the returned type of the field is defined as the original \( NF_2 \) (line 7). For a GCI in the form of \( C \sqsubseteq A \sqcap B \) (line 8), the returned type of the field is defined as the original \( NF_2 \) (line 9). For a GCI in the form of \( C \sqsubseteq A \sqcap B \) (line 10), the returned type of the field is defined as the original \( NF_2 \) (line 11). For a GCI in the form of \( C \sqsubseteq A \sqcap B \) (line 12), the returned type of the field is defined as the original \( NF_2 \) (line 13). For a GCI in the form of \( C \sqsubseteq A \sqcap B \) (line 14), the returned type of the field is defined as the original \( NF_2 \) (line 15). For a GCI in the form of \( C \sqsubseteq A \sqcap B \) (line 16), the returned type of the field is defined as the original \( NF_2 \) (line 17). For a GCI in the form of \( C \sqsubseteq A \sqcap B \) (line 18), the returned type of the field is defined as the original \( NF_2 \) (line 19). For a GCI in the form of \( C \sqsubseteq A \sqcap B \) (line 20), the returned type of the field is defined as the original \( NF_2 \) (line 21). For a GCI in the form of \( C \sqsubseteq A \sqcap B \) (line 22), the returned type of the field is defined as the original \( NF_2 \) (line 23). For a GCI in the form of \( C \sqsubseteq A \sqcap B \) (line 24), the returned type of the field is defined as the original \( NF_2 \) (line 25).

From line 13 to line 21, the algorithm deals with GCIs containing roles, which can be of the form \( NF_2 \) or \( NF_3 \) (such as University \( \sqsubseteq \forall \text{departments.Department} \)). In both cases, a field definition (e.g., departments) of the object type (e.g., University) and a field definition (departments) of the input type (UniversityFilter) are generated. However, for \( NF_3 \), the returned type of the field is defined as the original object type corresponding to the concept appearing on the right side of the GCI (line 20). For \( NF_2 \), the returned type is defined as a wrapped type, which is a list type (line 17). For instance, the departments field declaration for the University type is defined as [Department]. The algorithm deals with GCIs containing attributes in a similar way (line 22 to line 30). For example, the University object type has a field declaration, which is UniversityID: String.

We define a function \( \Phi \) for mapping a datatype that exists in the TBox to a scalar type in GraphQL. Due to the fact that current GraphQL supports five basic scalar types which are ID, Float, Int, Boolean, and String, our current implementation of function \( \Phi \) focuses on mapping datatypes \( \text{xsd:float}, \text{xsd:int}, \text{xsd:string} \) and \( \text{xsd:boolean} \) to scalar types Float, Int, String and Boolean, respectively. However, GraphQL allows users to define custom scalar types, and the values of such custom types should be JSON serializable. Therefore, our \( \Phi \) function can be extended in the future for mapping any datatype besides the above four types from a TBox into a custom scalar type in GraphQL.

By generating the GraphQL schema based on an ontology, the schema will contain object or interface types corresponding to concepts in the ontology, and field declarations corresponding to relationships in the ontology. When a GraphQL query is sent to the GraphQL server, a resolver function parses the query to determine which type in the schema is requested. It then parses the relevant definitions corresponding to such a type in the semantic mappings to retrieve data. For instance, if a query requests all the entities of the University object type, the resolver function parses the semantic mappings that are defined for the University concept to get information regarding how to access the underlying data sources.
Algorithm 1: Schema Generator

Input : $N_C$: normalized TBox $\mathcal{T}\mathcal{B}$; $\Phi$, mapping a datatype in $D$ to a scalar type
Output: a GraphQL schema $\mathcal{S}$

1. for $P \in N_C$ do
2. \quad $O_P = O_P \cup \{P\}$ // extend $\mathcal{S}$ with an empty object type, $P$
3. \quad $I_O = I_O \cup \{P; \text{Filter}\}$ // extend $\mathcal{S}$ with an empty input type, $\text{Filter}$
4. \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{Query}, \text{List}) \rightarrow [P]\}$
5. \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{Query}, \text{List}, \text{filter}) \rightarrow \text{Filter}\}$

6. for $t \in \mathcal{T}\mathcal{B}$ do
7. \quad if $t$ is of the form $P \sqsubseteq Q$ (i.e., $\text{NF}_1$) then
8. \quad \quad $I_t = I_t \cup \{Q\}$ // extend $\mathcal{S}$ with an empty interface type, $Q$
9. \quad \quad $I_O = I_O \cup \{Q; \text{Filter}\}$ // extend $\mathcal{S}$ with an input type, $\text{Filter}$
10. \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow Q\}$ // $r$: $\text{QFilter}$
11. \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow \text{QFilter}\}$ // $r$: $\text{QFilter}$
12. \quad \quad $\text{implementation}_\mathcal{S}(Q) = \text{implementation}_\mathcal{S}(Q) \cup P$ // declare that the object type $P$ implements $Q$
13. \quad else
14. \quad \quad if $P \sqsubseteq 1r.Q \in \mathcal{T}\mathcal{B}$ then
15. \quad \quad \quad Do nothing, this case will be handled in line 19 to line 21
16. \quad \quad else
17. \quad \quad \quad $\text{add following field/argument declarations to $P$ and $\text{Filter}$}/*$
18. \quad \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(P, r) \rightarrow Q\}$ // $r$: $\text{QFilter}$
19. \quad \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow \text{QFilter}\}$ // $r$: $\text{QFilter}$
20. \quad \quad \quad $\text{add following field/argument declarations to $P$ and $\text{Filter}$}/*$
21. \quad \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow \text{QFilter}\}$ // $r$: $\text{QFilter}$
22. \quad \quad \quad $\text{add following field/argument declarations to $P$ and $\text{Filter}$}/*$
23. \quad \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow \text{QFilter}\}$ // $r$: $\text{QFilter}$
24. \quad \quad \quad $\text{add following field/argument declarations to $P$ and $\text{Filter}$}/*$
25. \quad \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow \text{QFilter}\}$ // $r$: $\text{QFilter}$
26. \quad \quad \quad $\text{add following field/argument declarations to $P$ and $\text{Filter}$}/*$
27. \quad \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow \text{QFilter}\}$ // $r$: $\text{QFilter}$
28. \quad \quad \quad $\text{add following field/argument declarations to $P$ and $\text{Filter}$}/*$
29. \quad \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow \text{QFilter}\}$ // $r$: $\text{QFilter}$
30. \quad \quad \quad $\text{add following field/argument declarations to $P$ and $\text{Filter}$}/*$
31. \quad \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow \text{QFilter}\}$ // $r$: $\text{QFilter}$
32. \quad \quad \quad $\text{add following field/argument declarations to $P$ and $\text{Filter}$}/*$
33. \quad \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow \text{QFilter}\}$ // $r$: $\text{QFilter}$
34. \quad \quad \quad $\text{add following field/argument declarations to $P$ and $\text{Filter}$}/*$
35. \quad \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow \text{QFilter}\}$ // $r$: $\text{QFilter}$
36. \quad \quad \quad $\text{add following field/argument declarations to $P$ and $\text{Filter}$}/*$
37. \quad \quad \quad $\text{type}_\mathcal{S} = \text{type}_\mathcal{S} \cup \{(\text{PFilter}, r) \rightarrow \text{QFilter}\}$ // $r$: $\text{QFilter}$

4.4. The Intended Meaning of a Generated GraphQL Schema

In Section 4.3, we present the Schema Generator which takes a TBox representing an ontology as an input, to
generate a GraphQL schema. Such a GraphQL schema can describe how to access underlying data sources in which
the data can be annotated by the ontology. The underlying data can thus be viewed as an ABox for the TBox.
Therefore, a GraphQL query that conforms to this GraphQL schema can be considered as a query over the ABox.
To make this intention more formal we consider an ABox $A$ as a finite set of assertions of the form $P(x), R(x, y)$ or
$A(x, z)$, where $P \in N_C$, $R \in N_R, A \in N_A$, $x$ and $y$ are instance names, $z$ are literals. Listing 7 illustrates an example
ABox based on the TBox in Listing 6.
Let $O$ be an ontology represented by a TBox $T$; let $S$ be a GraphQL schema over $(F, A, T, S)$ generated by Algorithm 1 based on $T$; let $Q$ be a GraphQL query over $(F, A, T, S)$ such that $Q$ conforms to $S$. Evaluating $Q$ over underlying data sources that are instantiated in terms of $O$ can be defined as retrieving an ABox $A$ based on $T$:

- If $Q$ requests an object or an interface type $t$ with a field $f$ of which the returned type is a scalar type $s$ or the wrapping type $[x]$ (i.e., $t \in O \cup I_T$, $f \in F$, $s \in S$, and $(t, f) \mapsto s \in type_S^E$ or $(t, f) \mapsto [x] \in type_S^E$), we can find the corresponding assertions in the ABox $A$ of forms: $t(x)$ and $f(x, z)$;

- If $Q$ requests an object or an interface type $t_1$ with a field $f$ of which the returned type is another object or interface type $t_2$ or the wrapping type $[t_2]$ (i.e., $t_1, t_2 \in O \cup I_T$, $f \in F$, and $(t_1, f) \mapsto t_2 \in type_S^E$ or $(t_1, f) \mapsto [t_2] \in type_S^E$), we can find the corresponding assertions in the ABox $A$ of forms: $t_1(x)$, $t_2(y)$ and $f(x, y)$.

For instance, given the query (as shown in Listing 3) and the above ABox, University(university_1), UniversityID(university_1, "ul"), UniversityID(university_2, "u2"), head(d1, "Harry, Potter"), head(d2, "Sheldon, Cooper"), head(d3, "Paul, Atreides"), head(d4, "Jack, Lee") are supposed to be retrieved. The above definition presents the meaning of the GraphQL schema generated based on a TBox for evaluating GraphQL queries. The definition relies on the Schema Generator where for each concept, the algorithm creates a corresponding type with the same name of the concept, same for roles and attributes. This guarantees to find the corresponding assertions from the ABox. However, in practice, as we presented in Section 2.3.2, how a GraphQL query retrieves data over the underlying data sources, depends on how the resolver function is implemented when we construct GraphQL servers. In the next section, we present how resolver functions can be implemented in a generic way based on semantic mappings.

5. Generic GraphQL Resolver Function

In general, there are two styles for implementing resolver functions for a GraphQL server. One option is to implement one resolver function per type (object or interface) defined in the GraphQL schema, where such a function states how to fetch the data to populate relevant fields. For instance, since the Query type in Listing 1 has four field definitions (UniversityList, DepartmentList, AuthorList, and ProfessorList), we may provide four resolver functions for getting entities of the University, Department, Author and Professor types from underlying data sources, respectively. The other option is to provide a resolver function for every field of every type defined in the GraphQL schema, such that this resolver could return data for this field of any type. In our framework, we adopt the first style because it can be easily generalized based on semantic mappings. That is, we implement a generic resolver function that can be used to populate objects of any object type or interface type, and can be viewed as a built-in function of the GraphQL server. In Section 5.1, we introduce how a GraphQL query is represented by Abstract Syntax Trees (ASTs), in which one represents query fields and others represent the filter expression. Section 5.2 introduces the RDF Mapping Language (RML), which is used for representing semantic mappings, and Section 5.3 describes the components of the generic resolver function. In Section 5.4, we present the core algorithm for the generic resolver function, which is responsible for accessing underlying data sources based on semantic mappings.
In general, a GraphQL query can be represented using a single AST that contains nodes representing the fields requested in the query, and also contains additional nodes for the input arguments that may be used for each of these fields. In our approach, we assume that each query accepts an input argument which captures the notion of a filter condition. Therefore, we specify the query evaluation in two steps: (i) evaluating for a filter condition, which is represented via an input argument that is defined as an input object type in the schema, (ii) evaluating for those fields that are requested in the GraphQL query. For instance, in the query example shown in Listing 3, the field having a filtering condition is different from the requested fields (the former is UniversityID while the latter includes departments and head). In the evaluation step for the filter condition, the identifier information of the filtered out instances of the requested type (i.e., University) are obtained after accessing the underlying data sources. In the next step, the underlying data sources are accessed again to retrieve only the requested fields for the filtered instances. Therefore, to enable such two steps in the query evaluation, we use multiple ASTs to represent a GraphQL query (cf. Figure 3, these two ASTs represent the query shown in Listing 3), one of which captures the input argument structure (Figure 3a), and the other of which captures the structure of the query, including the requested fields and their types (Figure 3b). More specifically, every node in such ASTs represents either a named type (i.e., object type, interface type, input type, or scalar type), a wrapping type, or a field. Additionally, ASTs that represent input arguments also contain nodes that represent the values of scalar-typed fields (e.g., "u1" in the AST shown in Figure 3a). The types (i.e., UniversityFilter, StringFilter, String) or wrapping types (i.e., [University], [Department]) are drawn with rectangle nodes. The fields (i.e., UniversityID, _eq, departments, head) are drawn with rounded rectangle nodes.

In practice, a filter condition is converted into disjunctive normal form (DNF). A query result in DNF contains data formed by the union of data that satisfies each disjunct. Therefore, in the step of evaluating for a filter condition: (i) multiple ASTs are generated where each represents one of the disjuncts, (ii) the underlying data source are accessed several times to obtain instances satisfying each disjunct, (iii) a union of identifier information for these instances of the requested type is returned.

### 5.2. RDF Mapping Language (RML)

RML is a declarative mapping language for linking data to ontologies [30]. An RML document has one or more Triples Maps, which declare how input data is mapped into triples of the form (subject, predicate, object).
An example of RML mappings is shown in Listing 8. A Triples Map contains the following three components (Logical Source, Subject Map and a set of Predicate-Object Maps). A logical source declares the source of input data to be mapped. It contains definitions of source that locate the input data source, reference formulation declaring how to refer to the input data, and logical iterator declaring the iteration loop used to map the input data. For instance, line 2 to line 6 in Listing 8 constitute the definition of a logical source. The definition declares that the data source is a JSON-formatted data source on the Web and also describes the way of iterating the JSON-formatted data (line 5). A subject map declares a rule for generating subjects when transforming

```xml
<UniversityMapping>
  rr:logicalSource {
    rml:source "http://example.com/universities.json";
    rml:referenceFormulation ql:JSONPath;
    rml:iterator "$\cdot data\cdot universities\cdot[*]";
  };
  rr:subjectMap {
    rr:template "http://example.com/university/{uid}";
    rr:class schema:University;
  };
  rr:predicateObjectMap {
    rr:predicate schema:UniversityID;
    rr:objectMap {
      rml:reference "uid";
    };
  };
  rr:predicateObjectMap {
    rr:predicate schema:departments;
    rr:objectMap {
      rr:parentTriplesMap <DepartmentMapping>
      rr:joinCondition {
        rr:child "uid";
        rr:parent "university_id";
      };
    };
  };
  rr:predicateObjectMap {
    rr:predicate schema:head;
    rr:objectMap {
      rml:reference "HEAD";
    };
  };
</DepartmentMapping>
</UniversityMapping>
```

Listing 8 Example of RML mappings transforming university domain data, defined based on the example ontology as shown in Figure 1.
underlying data into triples, including how to construct URIs of subjects (e.g., line 8) and specifying the concept to which subjects belong (e.g., line 9). A predicate-object map consists of one or more predicate maps declaring how to generate predicates of triples (e.g., line 12), and one or more object maps or referencing object maps defining how to generate objects of triples. An object map can be a reference-valued term map or a constant-valued term map. The former declares a valid reference to a column (relational data sources), or to an object (JSON data sources). The latter declares the value of the object as constant data. For instance, line 39 to line 41 make up a reference-valued term map. Line 19 to line 25 constitute a definition of a referencing object map including the join condition based on two triples maps. A referencing object map refers to another triples map (called a parent triples map) by using a \texttt{rr:joinCondition} property to state the join condition between the current triples map and the parent triples map. A join condition contains two properties, \texttt{rr:child} and \texttt{rr:parent}, of which the values must be logical references to logical sources of the current triples map and the parent triples map, respectively.

5.3. Components of the Generic Resolver Function

We show the basic technical components of the generic resolver function including \texttt{QueryParser} and \texttt{Evaluator} in Figure 4. In Algorithm 2, we show the generic resolver function. The inputs to the generic resolver function are a GraphQL schema, a GraphQL query and semantic mappings. The GraphQL query and schema are inputs of the \texttt{QueryParser}. The \texttt{QueryParser} parses a query including a filter expression given as an input argument, and outputs the corresponding ASTs (Figure 3) for the input argument and the query structure, respectively (shown as arrows \(1\) and \(2\) in Figure 4). As mentioned in Section 5.1, in our practical solution a filter condition is converted into disjunctive normal form. In Algorithm 2, the \texttt{QueryParser} parses the query, converts a filter expression into a union of conjunctive expressions, and generates an AST for each conjunctive expression and an AST for the query structure (line 2). Then, the filter expression (line 5 to line 7 in Algorithm 2, frame \(a\) in Figure 4) and the query fields (line 9 and line 13 in Algorithm 2, frame \(b\) in Figure 4) are evaluated. The \texttt{Evaluator} is responsible for sending requests to underlying data sources and fetching data according to an AST. During evaluation of the filter expression, for each AST representing a conjunctive (sub-)expression, an evaluator is called to request data that satisfies the conjunctive (sub-)expression (line 6). After a call to an evaluator based on an AST (filter\_ast in line 6), data representing the requested type, which contains identifier information, is returned (identifier\_info in line 6). Taking the query in Listing 3 represented by the ASTs shown in Figure 3 as an example, the requested type is \texttt{University} and data that can identify university instances is supposed to be returned in identifier\_info. Such identifier information is captured in semantic mappings, which are used to construct the URIs for subjects where such subjects represent instances of the \texttt{University} concept. For instance, in line 8 of the RML mappings example in Listing 8, the values of the \texttt{aid} attribute of the underlying data source are used to construct URIs of subjects representing instances of the \texttt{University} concept. The identifier information returned by evaluating each filter\_ast is merged into filtered\_identifiers (line 7). During evaluation of the query fields, such merged identifier information is taken into account in the call to the evaluator of the query fields (line 9 in Algorithm 2, arrow \(3\) in Figure 4).

As mentioned in Section 4.3, by generating the GraphQL schema based on an ontology, we can therefore, for each object or interface type and each field declaration, find the corresponding concept and relationship in the ontology. Since such concepts and relationships are used to define semantic mappings, when a generic resolver function

![Figure 4. Technical components in the generic resolver function.](image-url)
Algorithm 2: Generic Resolver

Input: a GraphQL query: `query`; a GraphQL schema: `schema`; the semantic mappings: `triples_maps`

Output: a list of objects of the type to be queried

1. Initialize an empty list: `query_result`
2. Call `QueryParser` taking `query` and `schema` as inputs, to get ASTs: `filter_asts, query_ast`
3. If `filter_asts` is not Empty then
   1. Initialize an empty set: `filtered_identifiers`
   2. For each `filter_ast` in `filter_asts` do
      1. Call `Evaluator` taking `filter_ast` and `triples_maps` as inputs: `identifier_info`
      2. Merge `filtered_identifiers` and `identifier_info`: `filtered_identifiers`
   3. If `filtered_identifiers` is not Empty then
      1. Call `Evaluator` taking `query_ast, triples_maps` and `filtered_identifiers` as inputs: `query_result`
   4. Else
      1. Do nothing, there is not any instance from data sources satisfying the filter condition.
   5. Else
      1. /* there is not an input argument given to the query */
      2. Call `Evaluator` taking `query_ast, triples_maps` as inputs: `query_result`
4. Return `query_result`
Algorithm 3: Evaluator

Input: an Abstract Syntax Tree: \texttt{ast}; the semantic mappings: \texttt{triples\_maps}; the referencing data: \texttt{ref}; the identifiers for filtered out result: \texttt{filtered\_ids}

Output: result of evaluating a filter expression or query fields

1. Initialize an empty list: \texttt{result}
2. get the root type and query fields from \texttt{ast}: \texttt{root\_type, query\_fields}
3. if \texttt{triples\_maps is Empty} then
   4. get relevant triples maps based on the \texttt{root\_type}: \texttt{triples\_maps}
5. for \texttt{tm in triples\_maps} do
   6. Initialize an empty list: \texttt{referencing\_poms}
   7. Initialize three empty lists: \texttt{pred\_attr, pred\_const, pred\_template}
   8. get the logical source from \texttt{tm}: \texttt{source}
   9. get all the predicate-object maps from \texttt{tm} based on \texttt{query\_fields}: \texttt{queried\_poms}
10. for \texttt{pom in queried\_poms} do
   11. if \texttt{object\_map in pom is a reference-valued term map then}
       12. extend \texttt{pred\_attr} with a map between the predicate and column/attribute
   13. if \texttt{object\_map in pom is a constant-valued term map then}
       14. extend \texttt{pred\_const} with a map between the predicate and data value, type
   15. if \texttt{object\_map in pom is a template-valued term map then}
       16. extend \texttt{pred\_template} with a map between the predicate and template
   17. if \texttt{object\_map is a referencing-object map term map then}
       18. extend \texttt{referencing\_poms} with \texttt{pom}
   19. parse \texttt{ast} and get the filter expression: \texttt{filter\_expr}
   20. localize \texttt{filter\_expr} based on \texttt{pred\_attr, pred\_const, pred\_template, local\_filter}
   21. access the data source based on \texttt{source, local\_filter, ref, filtered\_ids: temp\_result}
   22. if \texttt{temp\_result is not Empty} then
       23. annotate \texttt{temp\_result} based on \texttt{pred\_attr, pred\_const, pred\_template}
       24. for \texttt{(pred, object\_map) in referencing\_poms} do
           25. get the sub tree from \texttt{ast} based on \texttt{pred: sub\_ast}
           26. parse \texttt{object\_map: parent\_triples\_map, join\_condition}
           27. parse \texttt{join\_condition: child\_field, parent\_field}
           28. get the referencing data from \texttt{temp\_result on child\_field: child\_data}
           29. \texttt{ref = (child\_data, parent\_field)}
           30. call \texttt{Evaluator based on sub\_ast, parent\_triples\_map, ref, parent\_data}
           31. join \texttt{temp\_result and parent\_data} based on \texttt{join\_condition, pred: temp\_result}
       32. \texttt{merge result and temp\_result: result}
   33. return \texttt{result}

fields, \texttt{filter\_ids}, being a NULL value or having at least one element, is a necessary argument (line 21, arrow (a) in Figure 5). A NULL value represents the fact that the GraphQL query does not include an input argument. After obtaining the data from the underlying data sources, the data is serialized into JSON format (key/value pairs) in which the keys are predicates stated in the predicate-object map (line 23), where each predicate corresponds to a field in the GraphQL schema. In the next step, the algorithm iterates over predicate-object maps in which the object map refers to another triples map (called a parent triples map) (line 24 to line 31). An evaluator is called again to fetch data based on this parent triples map (line 30, arrow (4) in Figure 5). For the query example, the parent triples map refers to the \texttt{DepartmentMapping}. Since such a referencing-object map definition states the join condition between the current triples map (\texttt{UniversityMapping}) based on \texttt{child\_field (uid)} and the parent triples map (\texttt{DepartmentMapping}) based on \texttt{parent\_field (university\_id)} (line 21 to line 23 of the mappings in Listing 8), we can pass referencing data (\texttt{ref}), which contains the data obtained according to the current triples map and \texttt{parent\_field}, to the call of an evaluator when we fetch data according to the parent triples map (line 30). Such referencing data is taken into account, in the recursive call to an evaluator, when the request is sent to the underlying data sources (line 21, arrow (a) in Figure 5). After the data is obtained according to the parent triples
map (arrow (c) in Figure 5), it is joined with data obtained according to the current triples map (line 31, frame (A) in Figure 5).

6. Related Work

The widely used Semantic Web-based techniques and the recently developed GraphQL have led to a number of works relevant to our GraphQL-based framework for data access and data integration. We extend the summary of approaches presented in [31] by adding several new related approaches and new perspectives on the comparison. Table 2 summarizes these systems and our approach. These systems can be divided into two categories, namely OBDA-based systems and GraphQL-based systems. The former group contains Morph-RDB [32, 33], Morph-Csv [34], Ontop [35, 36], Squarrel [37] and Ontario [38]. The latter group consists of GraphQL-LD [39], HyperGraph [40], UltraGraphQL [41, 42], Morph-GraphQL [31], Ontology2GraphQL [43] and our OBG-gen. OBG-gen can also be categorized as an OBDA-based system in the first group. In addition to the two groups described above, there is another system that is related to our work. It is OBA [44], which is an ontology-based framework that facilitates the development of REST APIs for knowledge graphs.

As a new perspective to the summary in [31], all the approaches (except for GraphQL-LD) have two processes: (i) the service setup (preparation) process and (ii) the query answering process. During the service setup process, all OBDA-based approaches need semantic mappings as input. In these systems, semantic mappings are used in a similar manner to represent differences between global and local schemas, namely mapping translations as highlighted in [16]. Some approaches take additional resources as inputs. Morph-Csv uses CSVV8 to annotate tabular data. OBG-gen needs an ontology and semantic mappings together in order to generate a GraphQL server that is intended not only for semantics-aware data access but for data integration.9 Another system that also uses ontologies in the service setup process is OBA. OBA generates an OpenAPI Specification (OAS)10 based on ontologies. It is also highlighted in [16] that the diversity of how underlying data sources provide data brings challenges to mapping translations. For instance, REST is a popular architecture for web services and is commonly used for Web-based applications to provide data since 2000. GraphQL becomes an alternative since 2012. In this respect, OBA, OBG-gen

---

8CSVV is used to annotate CSV files with JSON metadata (https://csvv.org).
9Morph-GraphQL requires semantic mappings to generate a GraphQL server intended for data access. It does not consider data integration scenarios where integrated views are required.

and Morph-GraphQL explore how semantic resources (i.e., ontologies and semantic mappings) can be used to provide access to data that is provided by Web APIs. For the other GraphQL related work, Ontology2GraphQL needs a meta model for the GraphQL query language and requires an ontology following the meta model for generating the GraphQL schema. HyperGraphQL requires no inputs during the service setup process, but the developer must build the GraphQL server from scratch. UltraGraphQL, based on HyperGraphQL, requires RDF schemas of SPARQL endpoints for bootstrapping the GraphQL server. In actuality, GraphQL-LD does not require any GraphQL servers, but instead focuses on how to represent GraphQL queries using SPARQL algebra and how to convert the results of a SPARQL query into a tree structure in response to a GraphQL query.

For the query answering process, OBDA-based approaches (i.e., Morph-RDB, Morph-CSV, Ontop, Squerall and Ontario) accept SPARQL queries and translate them into specific queries. Morph-RDB handle underlying data stored in relational databases, while Morph-CSV deals with data stored in CSV files. Morph-RDB and Morph-CSV translate SPARQL queries into SQL queries. Ontario, Squerall and Ontop support heterogeneous data sources. These three systems can translate SPARQL queries into various queries according to the query languages of the underlying
data sources or queries accepted by data source wrappers. Our approach, OBG-gen, accepts relational data, tabular
data and JSON-formatted data as the underlying data. Moreover, OBG-gen can integrate data in different formats
from multiple sources, due to the generic resolver function implementation that can structure obtained data in
the JSON format according to the GraphQL schema. The remaining approaches are based on underlying data in
SPARQL endpoints and translate GraphQL queries into SPARQL queries (GraphQL queries for GraphQL-based
approaches, API requests for OBA). GraphQL-LD, HyperGraphQL, and UltraGraphQL require context information
expressed in JSON-LD. Such JSON-LD context information contains URIs of classes to which instances in the RDF
data belong.

In addition, we study relevant OBDA/OBDI and GraphQL benchmarks to conduct our experiments and eval-
uation. These benchmarks are Berlin SPARQL Benchmark (BSBM) [45], Norwegian Petroleum Directorate
Benchmark (NPD) [46], GTFS-Madrid-Bench [47], ForBackBench [48] and Linköping GraphQL Benchmark
(LinGBM) [49]. These OBDA/OBDI related benchmarks are built based on different use cases (BSBM for the e-
commerce use case, NPD for the oil industry, GTFS-Madrid-Bench for the transport domain, ForBackBench reusing
data from other benchmarks) and focus on testing different abilities of OBDA/OBDI engines. In more detail, the
BSBM benchmark aims to test and compare the performance of native RDF stores with engines implementing
SPARQL-to-SQL query translation. The NPD benchmark can be used to analyze OBDA system implementations
in terms of query rewriting, query unfolding and query execution. The GTFS-Madrid-Bench aims to test engines
focusing on virtualized access to heterogeneous data. The above three benchmarks commonly focus on testing en-
gines that contain query rewriting mechanisms, which are usually implemented by OBDA/OBDI engines. The For-
BackBench benchmark has a focus on both data integration scenarios and data exchange scenarios. In the former
scenarios, engines usually implement query rewriting mechanisms. While in the latter scenarios, engines usually
implement forward-chaining algorithms (e.g., [50, 51]) to populate a centralized data warehouse. Therefore, in con-
trast to the previous three benchmarks, ForBackBench focuses on comparing and analyzing systems across two
different mechanisms (i.e., query rewriting and forward-chaining algorithms). In terms of GraphQL-related bench-
marks, the LinGBM benchmark is the first one that can be used to study the behavior of GraphQL server imple-
mentations at scale [49]. It provides a scalable dataset regarding the University domain and specifies key technical
challenges (e.g., relationship traversal) of GraphQL server implementations. For the evaluation of our work (see
next section), among these OBDA/OBDI and GraphQL related benchmarks, we choose GTFS-Madrid-Bench and
LinGBM, respectively. The reasons are: (i) for the real case evaluation in the materials design domain, LinGBM can
guide us to characteristic the GraphQL queries to better compare and analyze the abilities of GraphQL systems; (ii)
by following the scenarios in LinGBM and GTFS-Madrid-Bench, we can test the ability of our approach to work
for general different domains.

7. Evaluation

In this section, we present an evaluation of the framework shown in Section 3. We consider a real case application
scenario in the materials design domain, and two synthetic benchmark scenarios based on the Linköping GraphQL
Benchmark (LinGBM)\(^{11}\) [49] and GTFS-Madrid-Bench\(^{12}\) [47], respectively. The main goals of the evaluation are:
(i) to validate that GraphQL can be used to assemble an integrated view of underlying data and manage requests to
underlying data sources in an ontology-driven data access and integration scenario; (ii) to validate that the approach
can work in general domains for data access and integration. Meanwhile, we intend to provide initial insights into
the query performance of our approach by comparing it with existing OBDA-based and GraphQL-based solutions
for data access and data integration. Therefore, the evaluation focuses on validating the generality and feasibility
of our approach, and aims to answer the following detailed research questions:

- **RQ1**: Can the generated GraphQL server provide integrated access to heterogeneous data sources? For instance
  in the real case application scenario, data from different sources may follow different models and is shared or
  queried in different ways.

\(^{11}\)https://github.com/LiUGraphQL/LinGBM

\(^{12}\)https://github.com/oeg-upm/gtfs-bench
– **RQ2**: How does the generated GraphQL server compare to other OBDA-based systems and other GraphQL-based systems in terms of query performance and its behavior for increasing dataset sizes?

– **RQ3**: Is the proposed approach, ontology-based GraphQL server generation, a general approach that can work in different domains for data access and integration?

In the first evaluation scenario based on the real case application scenario in the materials design domain, we aim to answer **RQ1** and **RQ2**. In the second and third evaluation scenarios based on the LinGBM and the GTFS-Madrid-Bench benchmarks, we aim to answer **RQ3** to validate the generability and feasibility of our approach. We performed all experiments on a server machine with Intel Xeon Gold 6130 @ 2.10GHz CPUs. The machine runs a 64-bit CentOS Linux 7 (Core) operating system. We reserved 8 CPU cores and 4GB memory for the experiments.

### 7.1. Real Case Evaluation

In the real case evaluation, we focus on a use case in the materials design domain where the task is data integration over two data sources, Materials Project [52] and OQMD (The Open Quantum Materials Database) [53].

**Motivation.** The materials science domain, like many other domains, is at an early stage when it comes to introducing Semantic Web-based technologies into its data-driven workflows. A large number of research groups and communities have thus developed a variety of data-driven workflows, including data repositories [54, 55] and data analytics tools. As data-driven techniques become more prevalent, more data is produced by computer programs and is available from various sources, which leads to challenges associated with reproducing, sharing, exchanging, and integrating data among these sources [56–60]. Figure 6 illustrates an example of searching for gallium nitride materials with the reduced chemical formula of GaN in three databases of the materials design domain, Materials Project [52], OQMD [53] and NOMAD (Novel Materials Discovery) [61]. As shown in the results, each of them contains a column that represents chemical composition, but with different column names or different insights (i.e., ‘Formula’ for Materials Project and NOMAD, ‘Composition’ for OQMD). The ‘Formula’ column for Materials...
Project actually represents the reduced chemical formula. More detailed information regarding the chemical composition can be found based on the value of the ‘Nsites’ column. For instance, for the second row of the result from Materials Project, we can derive that the unit cell formula is Ga$_2$N$_2$ based on the values of the ‘Formula’ and ‘Nsites’ columns. Meanwhile, the ‘Formula’ column for NOMAD represents the unit cell formula rather than the reduced chemical formula. Unlike the other two databases, OQMD contains a column for reduced chemical formulas, but with a different column name (‘Composition’). Such differences have to be addressed in order to integrate or exchange data from these data sources. Apart from such differences in terminology, the data that needs to be accessed or integrated from multiple data sources is typically heterogeneous in different models (i.e., relational data stored in relational databases, and hierarchical data stored in JSON data stores). In our previous work, we developed the Materials Design Ontology (MDO) [62] to enable ontology-driven data access and integration. Furthermore, we have applied our MDO and OBG-gen in the OPTIMADE (Open Database Integrations for Materials Design) [63] consortium which is a domain effort to make materials databases interoperable. As the work in the consortium is under development, our application is at the level of a proof of concept. Details are presented in [64, p. 141-148].

**Data.** We collect data from the Materials Project and OQMD representing five different types of real-world entities (Calculation, Structure, Composition, Band Gap and Formation Energy). We define semantic mappings (for all the systems, see the next paragraph) based on MDO to interpret such data. We collect data in the sizes of 1K, 2K, 4K, 8K, 16K and 32K from each database for populating the five entities. The size 1K means 1000 entities of each entity type. We represent this data in different formats such as tabular data for relational databases and for CSV files, and JSON-formatted data for JSON files. Additionally, for HyperGraphQL and UltraGraphQL in our evaluation, we create an RDF file based on RML mappings and MDO for each dataset setting. We have six dataset settings for the experiments, which are 1K-1K, 2K-2K, 4K-4K, 8K-8K, 16K-16K and 32K-32K. Taking 2K-2K as an example, for each entity type, the test data contains data in the size of 2K from Materials Project and 2K from OQMD, respectively.

**Systems.** We compare our tool, OBG-gen in two versions (OBG-gen-rdb and OBG-gen-mix) with four systems: Morph-RDB [33], Ontop [36], HyperGraphQL [40], and UltraGraphQL [42]. OBG-gen-rdb represents the case where the generated GraphQL server handles data in relational databases, and OBG-gen-mix represents the case where the generated GraphQL server handles data not only in relational databases but also data in JSON and CSV formats. They take different RML mappings as inputs. Morph-RDB and Ontop are representatives from the group of OBDA-based tools. They can access relational databases as data sources by translating SPARQL queries into SQL queries based on semantic mappings, written in R2RML. As for the group of GraphQL-related tools, we in-
tended to include Morph-GraphQL and Ontology2GraphQL in our evaluation. However, Morph-GraphQL fails to parse mappings; Ontology2GraphQL cannot be run due to a lack of detailed instructions regarding its setup. In the case of GraphQL-LD, since it focuses on querying Linked Data via GraphQL queries and a JSON-LD context using a SPARQL engine instead of a GraphQL interface, we did not consider it in our evaluation. Therefore, HyperGraphQL and its extension UltraGraphQL are the GraphQL engines that are included in our evaluation. They can query Linked Data that may be provided by local RDF files and remote SPARQL endpoints. The semantic mappings for all the systems in the evaluation are based on MDO. OBG-gen generates the GraphQL schema based on MDO. UltraGraphQL and HyperGraphQL use a modified version of the generated schema since they require directive definitions to specify the correspondences between query entries and the data. Figure 7 shows how the systems are configured in the evaluation. HyperGraphQL and UltraGraphQL are provided with the same RDF data for each dataset setting. OBG-gen-rdb is provided with two MySQL database instances hosting data from the Materials Project and OQMD respectively. Morph-RDB and Ontop are provided with one single MySQL database instance hosting data from the two sources. Conceptually, OBG-gen-mix is also provided with two database instances. However, each instance contains different formats of data such as data in a MySQL database, or in CSV or JSON files. More detailed, the instance for Materials Project has Composition data in JSON format and Band Gap data in CSV format. The instance for OQMD has Structure and Band Gap data in JSON format and Formation Energy data in CSV format. The data representing other entities for each instance is stored in MySQL database instances.

**Queries.** We create queries that cover different features, aiming to evaluate our system based on qualitative aspects regarding what functionalities the system can satisfy and quantitative aspects regarding how the system performs over different data sizes. Additionally, we use competency questions stated in the requirements analysis of MDO to create queries with domain interests. The features of queries without and with filter expressions are shown in Table 3 and Table 4, respectively. From the perspective of GraphQL, we consider which choke point a query covers. The details of choke points are introduced in LinGBM.13 These choke points are regarding the key technical challenges. We characterize all queries using the perspectives of choke points, domain interest (DI), and result size (RS). DI indicates that the query is a domain-interest query. Such a query corresponds to a relevant competency question stated in the requirements analysis of MDO. For RS, as the dataset grows, we consider whether the result size

Experiments and measurements. We evaluate the query execution time (QET) of the different systems over the six dataset settings. Separately for each query, we run the query four times and always consider the first run to be a warm-up, then take the averaged value of the remaining three runs. Figure 8 illustrates the measurements over the six data sizes per query (Q1–Q12). Figure 9 and Figure 10 illustrate the measurements of all systems per data size for queries without filtering conditions and with filtering conditions, respectively. The measures for all data sizes and all queries are available online. For UltraGraphQL, we have measurements only for queries Q1–Q4 because UltraGraphQL does not support queries with filtering conditions. For HyperGraphQL answering queries with filter expressions, we have only the measurement for Q6 because the system can only deal with filtering by resource IRIs.

Results and discussion. By analyzing the obtained measurements, we summarize three observations. The first observation is that both GraphQL servers generated by OBG-gen-rdb and OBG-gen-mix can answer all 12 of the queries covering different features (such as choke points). Therefore, the framework presented in Section 3 is feasible for data access and integration; this answers RQ1. Particularly, the GraphQL schema generated based on the ontology can provide an (integrated) view of underlying (heterogeneous) data; the generic resolver function based on the semantic mappings is capable of accessing heterogeneous data sources, combining the retrieved data (which may be in different formats), and structuring the data according to the GraphQL schema.

The second observation is regarding queries without filtering conditions (Q1–Q5) (cf. Figures 8 and 9). All of the systems have increases of QETs as the size of the dataset increases. However, Morph-RDB is less sensitive to the data size increase compared with other systems. UltraGraphQL and HyperGraphQL outperform other systems for some smaller datasets (e.g., UltraGraphQL’s QETs of Q1 and Q2, HyperGraphQL’s QETs for Q1 from 1K–1K to 4K–4K). We explain this by the fact that these two systems have additional context information declaring URIs of classes to which instances in the RDF data belong, which is unlike the other systems which have to make use of
semantic mappings to output queries to be evaluated against the underlying data sources. OBG-gen-rdb outperforms Morph-RDB for some queries in smaller datasets (e.g., Q1 in 1K-1K, Q5 in 1K-1K and 2K-2K). For some queries, OBG-gen-rdb and Morph-RDB have close QETs (e.g., Q2 in 1K-1K). Ontop outperforms the other two in smaller datasets (e.g., Q1 in 1K-1K to 8K-8K, Q5 in 1K-1K to 4K-4K), but is more sensitive to data size increase compared with Morph-RDB.

The third observation is regarding how OBG-gen-rdb, Ontop and Morph-RDB perform for queries with filter conditions (Q6–Q12) (cf. Figures 8 and 10). Ontop outperforms the other two engines in most cases but is more sensitive to increases in dataset size (e.g., Q9 from 1K-1K to 8K-8K). According to [35], Ontop has a mapping optimization step which is not included in the query execution period. This could be a reason why Ontop outperforms the other engines. OBG-gen-rdb and Morph-RDB behave similarly for Q6 with stable QETs and Q12 with slight increases, as the data size increases. As Table 4 shows, the result size of Q6 is a constant over all the datasets in different sizes. Additionally, the filter expressions for Q6 and Q12 are simpler compared with those of Q7–Q11. Therefore, the QETs for evaluating filtering expressions for Q6 and Q12 are less than those of Q7–Q11. For other queries (Q7–Q11) Morph-RDB outperforms OBG-gen-rdb, however the differences between the two systems are

Figure 8. Query Execution Time (QET) per query on materials dataset.
Figure 9. Query Execution Time (QET) per data size on materials dataset for queries without filtering conditions.

Figure 10. Query Execution Time (QET) per data size on materials dataset for queries with filtering conditions.
less than those for queries without filtering conditions (e.g., Q1–Q4). The filtering conditions in GraphQL queries
for OBG-gen-rdb and in SPARQL queries for Morph-RDB are written within WHERE clauses in SQL queries, thus
will be evaluated against the back-end databases. A similar observation is also found in [31] where the experiment
metrics shows that Morph-RDB outperforms other systems (e.g., Morph-GraphQL) as the size of dataset increase
due to the SPARQL to SQL optimizations [31].
Based on the second and the third observations, we can answer the research question RQ2. The GraphQL servers
generated by OBG-gen perform similarly compared with other systems for queries without filtering conditions, but
are more sensitive to the increase of datasets even they can outperform for some queries in smaller datasets. By
comparing OBG-gen-rdb, Ontop and Morph-RDB, we summarize the reasons as follows. As shown in Section 5, the
implementation of OBG-gen is based on representing a GraphQL query with Abstract Syntax Trees (Figure 3). In
this way, two basic requests are sent to underlying data sources to get the data with respect to the semantic mappings.
While for Morph-RDB and Ontop, based on semantic mappings, a SPARQL query is translated into a single SQL
query. For queries with filtering conditions, all the three engines (OBG-gen-rdb, Morph-RDB and Ontop) can take
the advantages of rewriting filter conditions into SQL queries so that the QETs do not show a significant increase as
the data size increases.

7.2. Evaluation based on LinGBM (Linköping GraphQL Benchmark)

To show the generalizability of our system, we conduct an evaluation based on LinGBM. LinGBM provides
tools for generating datasets (data generator)\(^\text{15}\) and queries (query generator),\(^\text{16}\) and for testing execution time and
response time (test driver).\(^\text{17}\)

**Data.** The dataset generated by the data generator is a scalable, synthetic dataset regarding the University domain,
including several entity types (e.g., University and Department). We generate data in scale factors (sf) 4, 20 and 100
where a scale factor represents the number of universities [49]. We then create three MySQL database instances to
store the data in these three scale factors, respectively. We use a modified version of the GraphQL schema provided
by LinGBM for our GraphQL server, and define RML mappings according to the work in Morph-GraphQL.\(^\text{18}\) The
modification part is regarding input object type definitions so that they can be used to represent filtering conditions.

**Queries.** The experiments are performed over eight query sets, where each set contains 100 queries that are gen-
erated using the LinGBM query generator based on a query template (QT). A query template has placeholders for
input arguments. The query generator can generate a set of actual queries (query instances) based on a query tem-
plate in which the placeholder in the query template is replaced by an actual value. We select eight query templates
(QT1–QT6, QT10 and QT11) for constructing eight query sets (QS1–QS8). We show an example query according
to QT5 in Listing 9. The other six query templates from LinGBM require GraphQL servers to have implementations
for functionalities such as ordering and paging which are not considered currently by OBG-gen. However, these
functionalities are interesting for future extension of OBG-gen.

**Experiments, results and discussion.** Same as the real case evaluation, we evaluate the query execution time
(QET) of our system on the three datasets. Each query from a query set is evaluated once. We show the average
query execution times for the different query sets in Table 6. Based on the obtained measurements, we observe that
our system has slight increases for QS1, QS2, QS4, QS6 and QS7 in terms of the average QETs. For QS3, the
average QET is stable for all the three datasets. For QT5, the increase from 0.51 seconds at data scale factor 20 to
13.85 seconds at data scale factor 100 is due to the dramatic increase in result size. More specifically, the queries
in QS5 and QS8 need to access the ‘graduateStudent’ table which increases dramatically in size from 50,482 rows
in the table (sf=20) to 252,562 (sf=100). This is the reason for the average QET of QS8 increasing in sf=100.
Additionally, each query in QS5 repeats a cycle two times (‘university’ to ‘graduateStudent’ to ‘university’) and
requests the students’ emails and addresses along the way. This causes the larger increase in average QET of QS5.

3 The above synthetic experiments indicate that our system can work in another domain than the materials science domain.

4 7.3. Evaluation based on GTFS-Madrid-Bench

5 We furthermore demonstrate the generalizability of our system by evaluating it against GTFS-Madrid-Bench, which is a benchmark for evaluating OBBI systems.

6 **Data, queries and systems.** The dataset provided by GTFS-Madrid-Bench is a scalable dataset regarding the Transport domain (the metro system of Madrid), including several entity types (e.g., Route, Stop, Shape and Trip). We use the data generator provided by GTFS-Madrid-Bench to generate data in scale factors (sf) 1, 5, 10 and 50. For instance, the dataset in sf 1 contains 13 instances for the Route type, 1,262 instances for the Stop type, 58,540 instances for the Shape type and 130 instances for the Trip type. An increase in sf from 1 to 5 results in an increase in the dataset size of 5 times (e.g., 65 instances for the Route type and 6,310 instances for the Stop type). Each instance is represented by a row in the corresponding relational table. These scale factors are also used for the experiments in [47]. We then create four MySQL database instances to store the data in these four scale factors, respectively. A total of 18 queries are included in the GTFS-Madrid-Bench benchmark that cover the different features of SPARQL 1.1. For conducting the experiment based on GTFS-Madrid-Bench, we select seven queries (Q1–Q5, Q9, Q13) to create corresponding GraphQL queries. Among these four queries, Q1 retrieves all the shape entities where each shape entity is a polygon associated with a trip; Q2 retrieves all the stop entities where the latitude is greater than a specific value; Q3 retrieves accessibility information of all stop entities; Q4 retrieves all the route entities and their associated agency entities; Q5 retrieves services that have been added after a specific date; Q9 retrieves trips and associated shapes with latitude higher than a specific value; Q13 retrieves all the accesses of the stations [47]. The other queries contain SPARQL 1.1 features such as order by, group by and distinct. Currently, OBG-gen does not implement functionalities to cover these features. However, these functionalities are interesting for future extension.

Experiments, results and discussion. Same as the previous two evaluation scenarios, we evaluate the query execution time (QET) of systems on different datasets. We show the measurements in Table 7. According to the measurements, both OBG-gen-rdb and Ontop show increases in QETs for all four queries as the dataset increases. However, as with the observation in the real case evaluation, Ontop behaves less sensitively to the increase in dataset. In terms of how the two systems behave for different queries, both engines spend more time to answer Q1 (without any filter conditions) and Q9 (with several relationship retrievals). For answering Q1, OBG-gen-rdb spends more than 3,600 seconds for scale factors 10 and 50. Although Ontop is able to answer Q1 in less time than OBG-gen, it cannot finish the execution because it runs out of the reserved 4GB memory for scale factor 50. More specifically, Q1 needs to access the ‘Shape’ table which increases dramatically in size from 58,540 rows in the table (sf=1) to 292,700 (sf=5) and furthermore to 585,400 (sf=10) and 2,927,000 (sf=50). For answering Q9, OBG-gen can only return query result for scale factor 1, while Ontop for just scale factors 1 and 5. Both engines have relatively stable QETs for Q4 that retrieves all the route entities without any filter conditions, and for Q5 that retrieves services with a filter condition. The corresponding ‘Route’ table is relatively small (e.g., 13 for sf 1 and 1,300 for sf 100). Q2 and Q3 retrieve all the station entities but with different filter conditions. The two engines spend more time to evaluate Q2 since the result size of Q2 is larger than that of Q3. OBG-gen has an obvious increase for answering Q13 from scale factor 10 to 50. This is because that the corresponding retrieved table, ‘Stop’ increases in size from scale factors 10 to 50 (12,620 rows to 63,100 rows).

7.4. Summary

For evaluating our approach, ontology-based GraphQL server generation, we conducted an experiment motivated by the materials design domain and experiments based on two synthetic benchmark scenarios (LinGBM and GTFS-Madrid-Bench). Based on the measurements of these experiments, we can answer the three research questions presented at the beginning of Section 7. Our approach can generate GraphQL servers for data access and data integration and can be used in various domains (RQ1 and RQ3). The other GraphQL interfaces, HyperGraphQL and UltraGraphQL, can be used for data integration to a limited extent due to the fact that they do not support various filter conditions. This means questions with filter conditions cannot be answered. By comparing our approach with other well-known systems (RQ2), we learn that our system can perform relatively similar to others (e.g., Morph-RDB) in terms of QETs for queries with filter conditions (as shown in Figure 10), and for some queries without filter conditions in smaller datasets (as shown in Figure 9). Morph-RDB and Ontop are both less sensitive to the data size increase. The reason for this can be explained by the fact that they have optimization techniques that enable queries to be executed in a shorter amount of time. For instance, Ontop has a mapping optimization step which is not included in the query execution period [35, 65]; Morph-RDB has a query rewriting optimization step where projections and selections are pushed down for removing non-correlated subqueries [32, 65]. However, our approach supports data integration where the underlying data is from different kinds of sources (i.e., OBG-gen-mix), in contrast to Morph-RDB that only support data integration where the underlying data is from relational databases.
This is due to the implementation of the generic resolver function presented in Section 5, that combines data from multiple sources according to a GraphQL schema, as an integrated view of underlying data. Moreover, OBG-genmix can integrate data where underlying data is provided in different ways. In contrast, the other systems require the underlying data to be materialized as RDF triple stores (e.g., UltraGraphQL and HyperGraphQL) or to be stored in one single database (e.g., Morph-RDB and Ontop).

8. Discussion and Future Work

We emphasize that our work aims to enable GraphQL for not only data access (as other GraphQL-based approaches) but also data integration, by automatically generating the server based on an ontology and semantic mappings. Our work presents the first solution to this problem. Essentially, our approach concentrates on providing data access and integration using an ontology in a GraphQL setting with an approach that provides support for practical applications. In this respect, our work fills a gap in GraphQL applications (e.g., [31, 39–41, 43]). Compared with existing GraphQL-based approaches (e.g., UltraGraphQL [41] and HyperGraphQL [40]) for data access, our approach provides more GraphQL query features by supporting arbitrary filtering conditions. Our work can also provide an alternative to build data access and data integration applications, in addition to existing OBDA or OBDI approaches [33–35, 37, 38] (e.g., users can write GraphQL queries).

It should be noted that our current effort of OBG-gen focuses only on the GraphQL language [1] features that support semantics-aware and integrated data access, namely how underlying data can be queried, rather than reflecting the semantics of a complex knowledge representation language in the context of GraphQL schemas. Therefore, not all description logic constructors are used, but rather only those that are necessary for data access via GraphQL. It would be worthwhile to investigate how to represent more complex description logic constructors within the GraphQL context. In the future we will follow the development of the GraphQL language and investigate if any new features for data access can be generated formally based on the description logic currently used by OBG-gen or whether a more expressive language is needed. One specific example is the formal generation of union types in GraphQL schemas, based on ontologies. This will necessitate updates to the schema generator algorithm and the generic resolver function. Another extension related to the schema generator algorithm is to extend the \( \Phi \) function which is responsible for translating a datatype in the DL TBox to a corresponding datatype in GraphQL. Our current work focuses on generating basic datatypes supported by GraphQL (e.g., String, Float, Integer). However, in GraphQL schemas, custom type definitions can be used to represent datatypes rather than above basic ones. We will extend the \( \Phi \) function to support translating more datatypes in the DL TBox into custom type definitions in GraphQL schemas.

In contrast to the query languages SQL and SPARQL, which have been specifically designed for relational databases and triple stores, respectively, and encompass a wide range of query features, the capabilities of the GraphQL query language are contingent on the definitions of GraphQL schemas and the implementation of resolver functions. In our work, we implement resolver functions in a generic manner. As a result, along with GraphQL schemas containing input type definitions, OBG-gen enables the support of arbitrary filtering conditions in GraphQL queries. Additional query features, including aggregates (group by, having), solution sequences and modifiers (order by, distinct, offset, limit), are not yet covered but are part of our planned future work. Another extension related to the generic resolver function is to support user-defined functions (e.g., a date normalization function) on underlying data, which is not implemented in our approach currently. To support this, the Function Ontology (FnO) [66] can be used during creating RML mappings. We will work on extending the generic resolver function to enable user-defined functions.

In this work, we conducted a query performance comparison, specifically evaluating query execution times, between our tool and various OBDA-based and GraphQL-based approaches. While our approach shows more ample query capabilities than other GraphQL-based methods, and demonstrates similar performance to other OBDA-based approaches (as demonstrated in Section 7), there is still room for optimizing query performance. We emphasize that we did such comparisons aiming at providing initial insights into the query performance. A direction for future work includes optimizing our generic resolver function to enhance query performance. This may involve adapting the mapping partition group rules recently proposed in [67].
From a practical standpoint, we plan to implement a search system for OPTIMADE in the materials design domain based on our approach. As we mentioned before, OPTIMADE aims to make materials databases interoperable. Our approach can provide an integrated view of data to increase the interoperability. This will result to achieve data integration over more data sources, by considering more material databases. Our previous work in [62] has shown the capability of MDO to represent an integrated view of data over several representative material databases.

9. Concluding Remarks

To leverage ontologies for generating GraphQL APIs to support semantics-aware data access and data integration, in this article, we have presented a GraphQL-based framework (Section 3) for data access and integration in which an ontology drives the generation of the GraphQL server. Our approach consists of a formal method to generate a GraphQL schema based on an ontology (Section 4), and a generic implementation of resolver functions (Section 5). In detail, ontologies play two roles in our approach: one is as an integrated view of underlying data sources for generating a GraphQL schema; the other is as a basis for defining semantic mappings on which the generic GraphQL resolver function is based. Generating a GraphQL schema based on an ontology rather than just semantic mappings (e.g., Morph-GraphQL) can ensure to have an integrated view of data in data integration scenarios. Such a schema does not need to be regenerated when new data sources are added, unless the ontology needs to be modified. We show the feasibility and usefulness of our approach in terms of using GraphQL for data integration and avoiding implementing a GraphQL server from scratch, based on a real-world data integration scenario motivated by the materials design domain (Section 7.1) and two synthetic benchmark scenarios, LinGBM and GTFS-Madrid-Bench (Sections 7.2 and 7.3). Additionally, we discuss the strengths and limitations of our approach, moreover show some directions for future work (Section 8).
